Abstract   In this article, Z-scheme NiO/α-MoO₃ p-n heterojunction is successfully synthesized by a facile hydrothermal route. The phase and nanostructures are researched through a series of characterizations, such as XRD, SEM, TEM, EDX, XPS and DRS. It is confirmed that the NiO nanoparticles are deposited homogeneously on one dimensional α-MoO₃ nanobelts and p-n heterojuction is constructed at the interface of α-MoO₃ and NiO. Photocatalytic activity of the as-synthesized photocatalysts is investigated by photodegradation of methylene blue (MB) under simulated solar light irradiation. Compared with bare α-MoO₃, the NiO/α-MoO₃ p-n heterojunction exhibits significantly improved photocatalytic activity and photostability for MB degradation. The improvement in the photocatalytic performance can be attributed to the optimization of the charge transport pathway offered by Z-scheme heterojunctions, which can promote the effective separation of electron-hole pairs. The results indicate that Z-scheme NiO/α-MoO₃ p-n heterojunction is a novel and efficient photocatalyst with potential application for the removal of organic contaminant in wastewater.

1. Introduction

The toxic and cancerogenic organic dyes have become one of the major problems for the drinking water due to the extracts of printing, textiles and extraction mills. Confronted with the difficult degradation of multifarious organic compounds, the development and utilization of photocatalysis technology is pressing (Li et al., 2020; Wang et al., 2020; Guo et al., 2021). In the past two decades, semiconductor catalysts such as ZnO, TiO₂, Fe₂O₃, NiO, WO₃, and SnO₂ have

attracted significant attention owing to their low toxicity, high stability and environmentally friendly (Ali et al., 2021; Yoon et al., 2021; Nguyen-Dinh et al., 2021; Rong et al., 2021). However, for the convenient and cost-efficient single-component photocatalyst, the photogenerated carriers can easily recombine, which directly causes the low quantum efficiency and poor photocatalytic activity (Dong et al., 2019; Gui et al.,2020; Dong et al.,2020; Zuo et al., 2021). Several strategies have been investigated to promote the photocatalytic performance which include element doping, noble metal functionalization, and heterostructured composite fabrication (Zhai et al., 2020; Mehmood et al., 2017; Zha et al., 2021; Li 2022). The design of new photocatalyst materials with the desired properties has become a popular research field.

α-MoO$_3$, a well-known n-type semiconductor, has attracted much attention on photocatalytic applications due to its unique structural and optical properties. Recently, α-MoO$_3$ with various morphologies and modifications have been prepared and studied (Zhang et al., 2019; Szkoda et al., 2018; Chiang et al., 2015). However, the challenge for promoting the catalytic activity of bare α-MoO$_3$ still exists, which mainly lies in enhancing the visible light absorption and reducing the recombination of charge carriers. In order to further degrade the adsorbed organic contaminants efficiently, α-MoO$_3$ has been applied in conjunction with other elements or semiconductors to form new compounds or heterojunctions. For example, Zhang et al. (Zhang et al., 2018) reported the functionalization of AuPd nanoparticles on the surface of α-MoO$_3$ nanowires leading to an enhanced photocatalytic activity (11.5 times higher than that of bare α-MoO$_3$) for the degradation of trichloroethylene. Phuruangrat et al. (Phuruangrat et al., 2016; Phuruangrat et al., 2017; Phuruangrat et al., 2016) synthesized Gd, Dy and Eu-doped α-MoO$_3$ nanobelts by hydrothermal method, which exhibited high visible-light-driven activity for photodegradation of MB. Feng et al. (Feng et al., 2017) combined α-MoO$_3$ nanobelts with AgBr to form a Z-scheme photocatalyst, resulting in the dramatic visible light absorption and improved photocatalytic performance in degrading RhB. Xi et al. (Xi et al., 2019) constructed a dye-sensitized MoO$_2$ incorporated α-MoO$_3$ photocatalyst, which displayed high RhB degradation efficiency under visible-light irradiation. Thus, it is necessary to construct the α-MoO$_3$-based photocatalysts to further shorten the degradation period and enhance photocatalytic efficiency.

P-n heterojunction constructed by combining a n-type semiconductor (electron-rich) with a p-type semiconductor (hole-rich) is one of the most effective methods to enhance the charge separation. Among the family of semiconductor materials, NiO, a p-type semiconductor, has been widely applied in the fabrication of p-n heterostructures with different n-type semiconductors. Up to now, a series of NiO-based composites have been studied, such as NiO/SnO$_2$ (Jayababu et al., 2019), TiO$_2$/NiO (Sun et al., 2016), NiO/Fe$_2$O$_3$ (Jana et al., 2018), ZnO/NiO (Li et al., 2018) and so on. However, to our best knowledge, there is rarely report on the preparation and photocatalytic performance of NiO/α-MoO$_3$ constructed p-n heterostructures. Notably, both the valence band (VB) and conduction band (CB) of NiO are more negative than those of α-MoO$_3$. We can introduce the appropriate band positions of NiO into α-MoO$_3$ to create a Z-scheme photocatalyst system, which will help decrease the electron-hole recombination of α-MoO$_3$ and enable us to obtain higher efficiency photocatalysts. In this work, we designed and successfully constructed a Z-scheme NiO/α-MoO$_3$ p-n heterojunction by a two-step hydrothermal route. The microstructure, elemental composition and optical property of the as-fabricated heterostructures were evaluated. The photocatalytic activity was estimated by using the degradation of the MB dye under simulated solar light irradiation. Finally, the possible mechanism for the photocatalytic process was proposed and discussed in detail.

2. Experimental procedures

2.1. Preparation of one dimensional α-MoO$_3$ nanobelts

In a typical procedure, 1.24 g of ammonium heptamolybdate tetrahydrate ((NH$_4$)$_6$Mo$_7$O$_{24}$·4H$_2$O) was dissolved into 50 mL pure water, followed by adding 5.0 mL nitric acid (HNO$_3$, 65%) in a dropwise manner. After continuous stirring for 30 min, the mixture was transferred to a Teflon-lined stainless-steel autoclave with capacity of 100 mL for hydrothermal treatment at 180 °C for 36 h. Upon cooling down the autoclave to room temperature, a white precipitate was collected by filtration, washed by distilled water and ethanol, and dried at 80 °C for 24 h.

2.2. Preparation of NiO/α-MoO$_3$ heterostructure

NiO/α-MoO$_3$ heterostructures were also prepared by a hydrothermal approach. NiO/α-MoO$_3$ heterostructures with different mass ratios of NiO powders (1 wt%, 3 wt% and 5 wt%) were described as follows: 0.24 g of as-synthesized α-MoO$_3$ was suspended into 40 mL pure water with ultrasonic concussion for 20 min, and then different mass ratios of Ni(NO$_3$)$_2$·6H$_2$O (0.01, 0.03 and 0.05 g) and 0.4 g of D-glucose monohydrate (C$_6$H$_{12}$O$_6$·H$_2$O) were put into the mixed solution under strong magnetic stirring for 15 min. Then the mixture was transferred to a 50 mL Teflon-lined stainless autoclave and heated at at 160 °C for 5 h. The product was centrifugally separated, washed several times with water/ethanol and then dried in vacuum at 70 °C for 24 h. Finally, the as-obtained materials were calcined in a muffle furnace at 400 °C for 3 h. The NiO/α-MoO$_3$ heterostructures with different mass ratios of NiO (1 wt%, 3 wt%, and 5 wt%) were labelled as 1% NiO/α-MoO$_3$, 3% NiO/α-MoO$_3$ and 5% NiO/α-MoO$_3$, respectively (EDS patterns could be seen in Fig. S1). For comparison, pure NiO was synthesised without adding of α-MoO$_3$ nanobelts.

2.3. Characterization

Characterization techniques are provided in the Supporting Information.

2.4. Photocatalytic activity

Photocatalytic experiments of the as-synthesized samples were examined by degrading MB in aqueous solution under simulated solar light irradiation of a 500 W Xe lamp. In a typical photocatalytic process, 0.01 g of each catalyst and 100 mL MB (10 mg L^{-1}) were added into the photocatalytic reactor. To achieve the adsorption–desorption equilibrium between the catalysts and MB dye, the solution was continuously stirred in the dark for 30 min. At periodic intervals (30 min), 2 mL of suspension was collected from the solution and separated through centrifuge to remove the photocatalyst particles. Finally, the concentration of leftover solution was analysed by the UV–vis spectrophotometer (UV-3600, Shimadzu). Recovery of photocatalyst was conducted by using methanol/acetic acid (95:5, v/v) solution. After the photocata-

lyst was contacted with the solvent completely, the photocatalyst was separated by centrifuge. To investigate the reproducibility of the photocatalyst, the photocatalyst after photocatalytic degradation was reused in experiments and the process was duplicated five times.

3. Result and discussion

The crystal structures of NiO/α-MoO₃ heterojunctions, α-MoO₃ nanobelts and NiO nanoparticles are studied by XRD analysis. As the XRD patterns revealed in Fig. 1, the diffraction peaks for bare α-MoO₃ are in accordance with JCPDS No.05–0508. The mainly characteristic peaks located in 2θ = 12.8°, 25.7° and 39.0° are indexed to (020), (040) and (060) crystal planes (Li et al., 2017), verifying the orthorhombic α-MoO₃ phase. Moreover, the pattern of NiO exhibits four diffraction peaks at about 2θ of 37.2°, 43.3°, 62.9° and 75.5°, which correspond to the crystal plane (111), (200), (220) and (311) of cubic NiO phase (JCPDS No. 47–1049) (Sun et al., 2016), respectively. It is worth to mention that all diffraction peaks of NiO/α-MoO₃ heterojunctions are matched well with the α-MoO₃ phase and no feature peaks of NiO are detected. The reason may be that there is few NiO in the nanocomposites and the diffraction peaks of α-MoO₃ can cover the NiO peaks (Li et al., 2017).

SEM, TEM and HRTEM are acquired to confirm the successful introduction of NiO nanoparticles on the α-MoO₃ nanobelts. Fig. 2(a-e) shows the typical SEM images of pure α-MoO₃, NiO/α-MoO₃ heterojunctions and NiO. The SEM results reveal that the pure α-MoO₃ material displays a belt-like structure with the length of 2–10 μm and width of 200–300 nm, and the ratio of length/width can reach as high as 50/1 (Fig. 2(a)). Pure NiO possesses a flower-like morphology with diameters ranging from 500 to 800 nm (Fig. 2(e)). Compared with pure α-MoO₃, it can be found that the surfaces of NiO/α-MoO₃ turn coarser which can be ascribed to the successful loading of the secondary NiO particles onto the α-MoO₃ substrates. However, with the increase of loading content, the independent NiO particles appear in the SEM image of 5% NiO/α-MoO₃ (Fig. 2(d)).
The TEM image (Fig. 2(f)) of the single NiO-functionalized α-MoO₃ nanobelt further confirms that NiO nanoparticles are uniformly dispersed on the surface of α-MoO₃ nanobelts. The HRTEM image of 3% NiO/α-MoO₃ is also acquired (Fig. 2 (g)). The interplanar spacings of 0.37 nm and 0.40 nm are clearly observed, which are indexed to the (001) and (100) planes of the α-MoO₃ crystal (Li et al., 2017). As for the lattice fringe of 0.21 nm, it can be assigned to the (200) plane of NiO crystal (Hou et al., 2014; Zheng et al., 2015). The synthetic processes for the NiO/α-MoO₃ heterojunctions are illustrated in Fig. 2(h). Under the hydrothermal conditions, linear or branched oligomers are formed by the partially dehydrated glucose, which decompose into a carbon shell coating on the surface of α-MoO₃ (TGA and DSC analyses could be seen in Fig. S2). In addition, the carbon shell has distribution of – OH groups on the hydrophilic surface of α-MoO₃ (Titirici et al., 2006; Wang et al., 2015; Demir-Cakan et al., 2009). The metal nickel ions (Ni^{2+}) conjugate with the –OH groups by an electrostatic attraction or coordination effect. Some Ni^{2+} ions agglomerate together to form larger clusters with the reaction time prolonging. Finally, the NiO/α-MoO₃ heterojunctions are obtained by oxidative calcination in air to remove the carbon.

Fig. 3(a-d) illustrates the corresponding elemental mappings of Mo, O and Ni of the 3% NiO/α-MoO₃ heterojunction, which reveals the different distributions of the three elements in the heterostructure. The mapping shows that the signal of Mo is mainly displayed in the core region, and the signal of Ni is distributed from the outer layer, which further confirms that the NiO/α-MoO₃ heterojunctions are successfully obtained. Meanwhile, the EDX analysis (Fig. 3(e)) demonstrates that the elements of the heterojunctions are composed of Mo, O, and Ni and no impurities are observed. The atomic ratios for Mo and Ni are about 17:1.

XPS analysis is conducted to confirm the chemical states of the elements for 3% NiO/α-MoO₃ and pure α-MoO₃. XPS survey spectrum (Fig. 4(a)) reveals that the heterojunction mainly contains Ni, Mo and O elements, which agrees well with EDX results. Fig. 4(b) gives the XPS spectra of the Ni 2p, which reveals two edges of Ni $2p_{1/2}$ and Ni $2p_{3/2}$ (Zheng et al., 2015; Jiang et al., 2019). The Ni $2p_{3/2}$ main peak and its satellite (856.3 eV and 863.3 eV) as well as Ni $2p_{1/2}$ main peak and its satellite (873.7 eV and 880.8 eV) are ascribed to the Ni^{2+} ions in NiO, suggesting the Ni^{2+} ions are dominant in the product (Jiang et al., 2019). The Mo 3d XPS spectrum (Fig. 4(c)) exhibits two peaks at binding energies of 232.5 and 235.7 eV, which relate to Mo $3d_{5/2}$ and Mo $3d_{3/2}$ in α-MoO₃, respectively (Sunu et al., 2004; Sui et al., 2015). However, the Mo 3d peaks in NiO/α-MoO₃ heterojunctions shift to higher energies, with the binding energies of Mo $3d_{5/2}$ and Mo $3d_{3/2}$ shifting to 232.9 and 236.1 eV, respectively. The Gauss fitting curves of the O 1s spectra (Fig. 4(d)) of pure α-MoO₃ and 3% NiO/α-MoO₃ contain two peaks centered at 530.6/531.0 eV and 532.1/532.5 eV, which come from the lattice oxygen in α-MoO₃ and chemisorbed oxygen site (Li et al., 2017; Yang et al.,2017), respectively. It is obvious that the O 1s binding energy peaks of 3% NiO/α-MoO₃ show a shift to higher value. The slight variation of Mo or O electronic structure may be attributed to the formation of heterojunction interface between two phases which would play a critical role in the photocatalytic process of the heterojunctions.

Fig. 1 XRD patterns of (a) α-MoO₃, (b) 1% NiO/α-MoO₃, (c) 3% NiO/α-MoO₃, (d) 5% NiO/α-MoO₃ and (e) NiO.

Fig. 2 SEM images of (a) α-MoO₃, (b) 1% NiO/α-MoO₃, (c) 3% NiO/α-MoO₃, (d) 5% NiO/α-MoO₃ and (e) NiO; TEM (f) and HRTEM (g) images of 3% NiO/α-MoO₃; (h) Schematic illustration for the preparation of the NiO/α-MoO₃ heterojunctions.

The optical absorption properties of α-MoO₃, NiO and a series of NiO/α-MoO₃ heterojunctions are investigated by UV–Vis diffuse reflectance spectroscopy (DRS) in Fig. 5(a).

The bare NiO has a pronounced light absorption in the wavelength region 200–800 nm because of its dark color (Li et al., 2021; Sabzehparvar et al., 2021). While for pure α-MoO₃, it
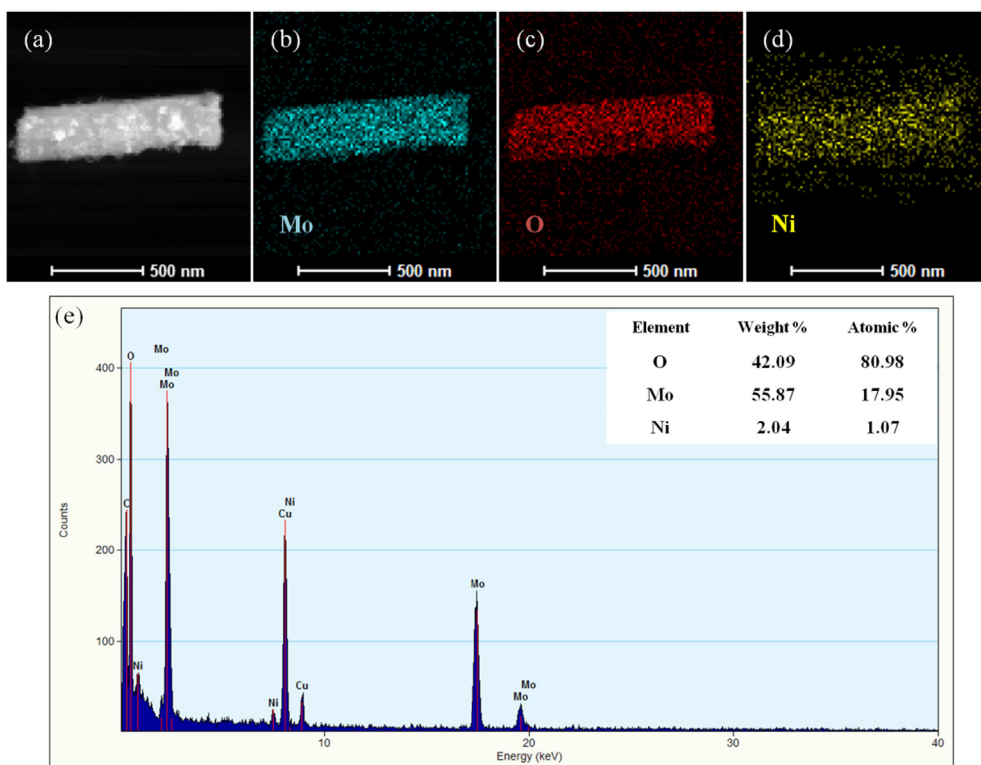

Fig. 3 The scanning TEM image (a) and corresponding elemental mappings (b-d) of Mo, O, and Ni of 3% NiO/α-MoO₃ heterojunctions, respectively; EDX image (e) of the heterojunctions.

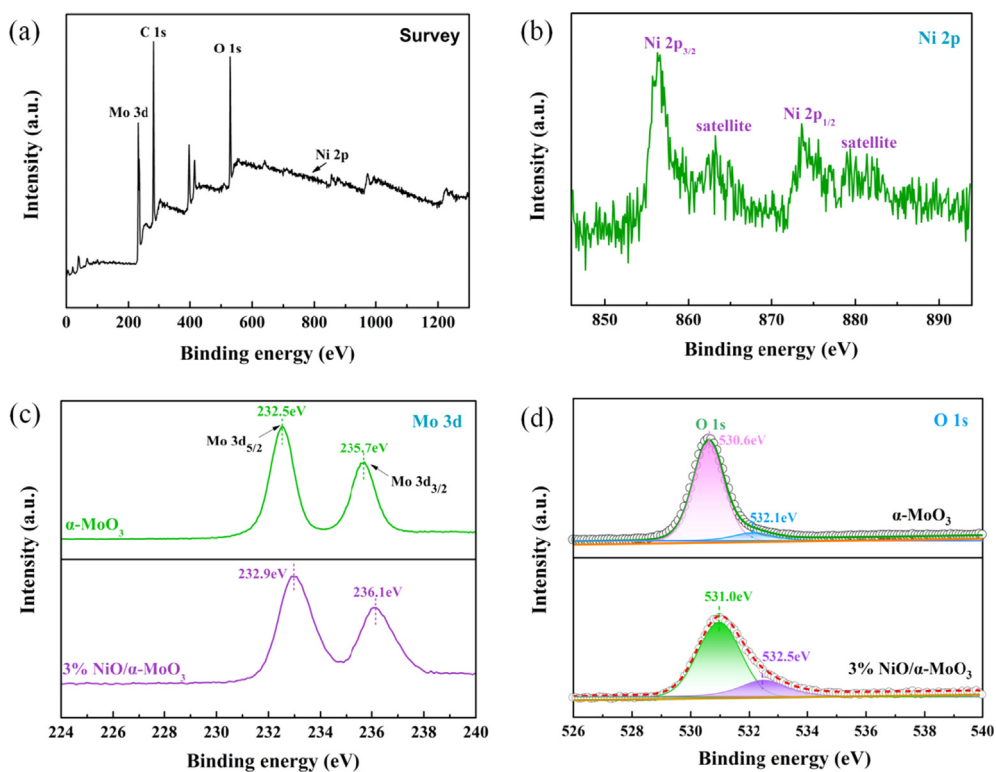

Fig. 4 Full survey scan spectra (a) and Ni 2p XPS spectra (b) of 3% NiO/α-MoO₃ heterojunction; high-resolution XPS spectra of Mo 3d (c) and O 1s (d) of bare α-MoO₃ and 3% NiO/α-MoO₃ heterojunction.

displays a steep absorption edge at 420 nm and exhibits the intrinsic absorption in UV region and the weak absorption band in visible wavelength. By contrast, the absorption edge of the composites shows an obvious shift towards the visible range upon decoration of NiO, which might be caused by the strong interactions between α-MoO$_3$ and NiO of the heterostructure (Sabzehparvar et al., 2021). The red shift of the absorption wavelengths is favorable for the NiO/α-MoO$_3$ heterojunctions to absorb light in the broader region and enhance the visible light photoresponse. The optical band gap can be calculated according to the Tauc equation: $(\alpha h\nu)^2 = A (h\nu - Eg)$. As shown in Fig. 5(b), the estimated band gaps of α-MoO$_3$ and NiO by the plot of $(\alpha h\nu)^2$ vs. hv are 3.25 and 3.08 eV (vs. NHE), respectively, which are identical with the previous studies (Sun et al., 2016; Li et al., 2017). To further get the band position of pure α-MoO$_3$ and NiO, XPS valence band spectra is employed to investigate the VB energy levels. As shown in Fig. 5(c), the maximum energy edges of VB density of states for pure α-MoO$_3$ and NiO are approximately at 3.27 eV and 0.53 eV (vs. NHE), respectively. Furthermore, the position of CB is calculated according to the formula: $Eg = E_{VB} - E_{CB}$. Thus, the CB values of α-MoO$_3$ and NiO are calculated to be 0.02 and −2.55 eV, respectively. According to the above computed results, the energy-levels of the semiconductors are worked out in Fig. 5(d). It reveals that the VB and CB positions of NiO are negative than those of α-MoO$_3$, demonstrating the suitable energy band structures for them to construct the heterostructure composites.

The photocatalytic activities of as-prepared samples are investigated by the MB photodegradation under simulated solar light irradiation. Fig. 6(a) shows the photodegradation efficiency of the photocatalysts. Obviously, for the blank experimental analysis, it can be seen that MB is hardly degraded under visible and catalyst-free conditions, which fully shows that MB is very stable in the aqueous solution. The MB removal efficiency of pure α-MoO$_3$ and NiO is only 41.3% and 49.8% in 2 h, respectively, implying the poor degradation efficiency of the pristine samples. While, after the addition of different amount of NiO, the photocatalytic performance is significantly enhanced. The photoactivity of the NiO/α-MoO$_3$ heterojunctions follows the order of 3% NiO/α-MoO$_3$ > 5% NiO/α-MoO$_3$ > 1% NiO/α-MoO$_3$, with the removal efficiency of 96.5%, 77.4% and 66.5%, respectively. The results show that 3% NiO/α-MoO$_3$ exhibits the best photocatalytic performance, and the MB is almost completely degraded after 2 h of light irradiation (Fig. 6(b)). The reaction kinetics of the MB degradation by different photocatalysts is fitted to a first order model and Fig. 6(c) displays the plot between $Ln(C_0/C)$ and reaction time. The corresponding apparent rate constants of the catalysts for MB degradation are 0.00375, 0.00515, 0.00903, 0.02685 and 0.01143 min^{-1}, respectively (Fig. 6(d)). Noticeably, the k value for MB degradation over 3% NiO/α-MoO$_3$ (0.02685 min^{-1}) is 7.16 folds than that of bare α-MoO$_3$ (0.00375 min^{-1}). To verify the universality of our catalysts, we selected some other organic contaminants, such as RhB and phenol, for photocatalytic degradation over 3% NiO/α-MoO$_3$. As exhibited in Fig. S3, 3% NiO/α-MoO$_3$ exhibits good photocatalytic activity towards other organic contaminants.

In addition to photodegradation efficiency, the photostability of the catalysts is also a very significant factor for practical applications. In order to evaluate the photostability and degradation rate for 3% NiO/α-MoO$_3$ heterojunction, the cycling runs in the MB degradation are carried out. Fig. 7

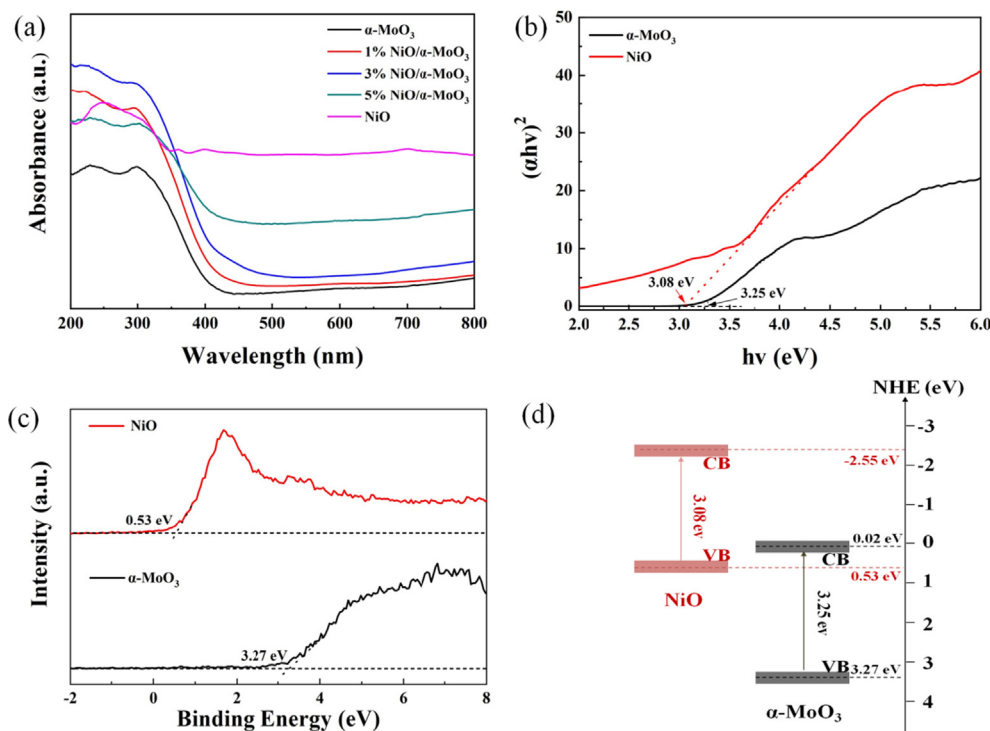

Fig. 5 (a) UV–vis DRS of α-MoO$_3$, NiO and a series of NiO/α-MoO$_3$ heterojunctions; (b) Eg values of α-MoO$_3$ and NiO; (c) XPS valence band spectrum for α-MoO$_3$ and NiO. (d) The band structure diagrams of α-MoO$_3$ and NiO.
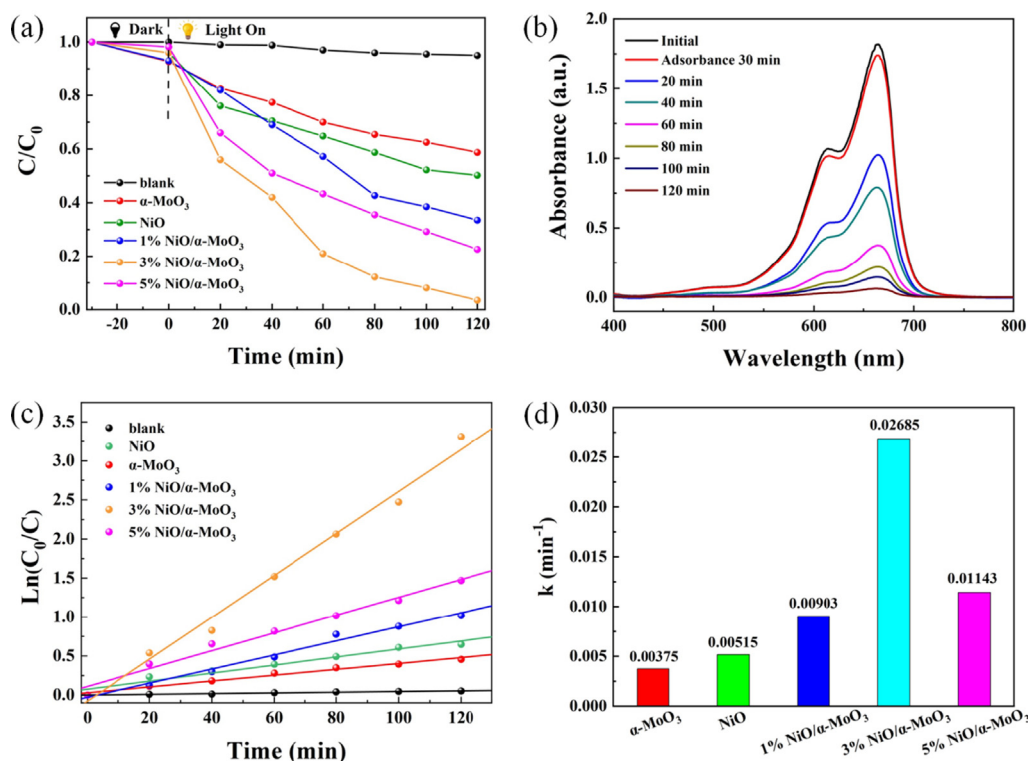

Fig. 6 (a) Photodegradation efficiency of MB over various photocatalysts; (b) Absorption spectra of MB with time using 3% NiO/α-MoO$_3$; (c) The pseudo-first-order reaction kinetics and (d) apparent rate constants of the photocatalysts for MB degradation.

(a) displays that the photocatalytic degradation rate of 3% NiO/α-MoO$_3$ heterojunction is retained at 94.3% after five successive experimental runs, confirming that 3% NiO/α-MoO$_3$ heterojunction is very stable during the photocatalytic degradation processes. No apparent crystalline structure and morphology's changes are observed in the XRD pattern (Fig. 7(b)) and SEM image (Fig. S4) of 3% NiO/α-MoO$_3$ after cyclicing experiment, which further demonstrates the significant stability of the photocatalyst. Furthermore, when compared with other reports for photodegradation of MB (Table S1), this work displays better photocatalytic degradation rate constant. Therefore, it can be inferred that the 3% NiO/α-MoO$_3$ heterojunction is a reusable photocatalyst for

application in treatment of organic pollutants from wastewaters.

Nitrogen adsorption–desorption isotherm curves of as-prepared photocatalysts are shown in Fig. 8(a). It can be seen that the loading of NiO nanoparticles on α-MoO$_3$ nanobelts results in an enhancement of specific surface area (13.32 m^2 g^{-1}) in comparison with pristine α-MoO$_3$ (7.34 m^2 g^{-1}). The heterojunction with the higher surface area can provide more active sites, thus improve the adsorption capacity and photo-catalytic degradation activities (Shi et al.,2020). To investigate the influence of NiO introduction on the behavior of charge carriers, several photo-electrochemical measurements including PL, photocurrent response measurement and EIS are car-

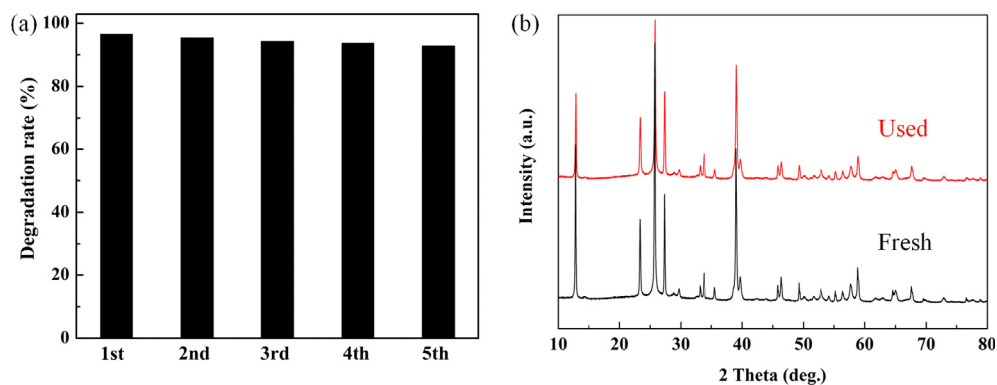

Fig. 7 (a) Cycling runs of 3% NiO/α-MoO$_3$ heterojunction for photodegradation of MB; (b) XRD patterns of 3% NiO/α-MoO$_3$ before and after 5 runs.

ried out to reveal the intrinsic charge separation characteristics. In Fig. 8(b), PL spectra is displayed to probe the photogenerated electron transfer of the α-MoO₃ and 3% NiO/α-MoO₃ heterojunction. Pristine α-MoO₃ has a strong emission peak centered at 460 nm, which possesses the strongest PL emission intensity. After the loading of NiO, the PL emission intensity of 3% NiO/α-MoO₃ exhibits a rapid decrease compared with the pure α-MoO₃. Ordinarily, a weaker PL intensity implies a lower recombination rate of photoinduced electron–hole pairs (Guo et al., 2021; Wang et al., 2021). Thus, the decoration of NiO can provide more electron-hole capture sites, which leads to enhanced photocatalytic activity. The transient photocurrent response spectra of 3% NiO/α-MoO₃ and bare α-MoO₃ are recorded for four intermittent light on–off circulations in Fig. 8(c). The pure α-MoO₃ has a poor light current response of about 0.01 $\mu A/cm^2$, while the photocurrent response of 3% NiO/α-MoO₃ is much higher at about 0.04 $\mu A/cm^2$. This indicates the faster transfer rate of photogenerated electrons of 3% NiO/α-MoO₃ heterojunction, leading to a more efficient carriers transfer process (Zhang et al., 2021; Zhou et al., 2021). Moreover, the EIS Nyquist plots of the photocatalysts are exhibited in Fig. 8(d) and 3% NiO/α-MoO₃ heterojunction shows the smaller arc radius than bare α-MoO₃. The result further indicates that the heterojunction possesses a lower charge-transfer resistance and thus a faster charge-transfer rate in the photodegradation process (Lu et al., 2019).

For the purpose of explore the main reactive species of 3% NiO/α-MoO₃ during MB photodegradation, the trapping experiments are implemented with ethylenediamine tetraacetate (EDTA-2Na) as the hole (h^+) scavenger, benzoquinone (BQ) as the superoxide radical ($\bullet O_2^-$) scavenger and isopropanol (IPA) as the hydroxyl ($\bullet OH$) scavenger. As displayed in Fig. 9(a), when no scavenger is added in the system, the degradation rate of 3% NiO/α-MoO₃ is still 96.5% within 120 min. In contrast, when EDTA-2Na, BQ and IPA are added, the degradation rate is significantly restrained, indicating that h^+, $\bullet O_2^-$ and $\bullet OH$ are all the key active species in the photodegradation process. Spintrapping ESR technology is conducted to further verify the $\bullet O_2^-$ and $\bullet OH$ generated in the photocatalytic processes. The ESR signals of 3% NiO/α-MoO₃ under xenon lamp irradiation and in the dark are presented in Fig. 9(b). No characteristic peaks of active species can be observed under dark conditions. However, six clear signals of $\bullet O_2^-$ appear under xenon lamp irradiation, which proves the presence of $\bullet O_2^-$ in the photodegradation process over 3% NiO/α-MoO₃ heterojunction photocatalyst. Moreover, when 3% NiO/α-MoO₃ heterojunction is irradiated under xenon lamp, four characteristic signals of $\bullet OH$ with intensity of 1:2:2:1 are detected. The ESR results reveal that both $\bullet O_2^-$ and $\bullet OH$ are involved, and they can play important roles in decomposing MB dye (Li et al., 2020).

Considering the experimental results described above and the calculated band gap structures, the proposed mechanism of NiO/α-MoO₃ heterojunction under light irradiation is presented in Fig. 10. Due to the well-matched VB and CB positions, a heterojunction can form between α-MoO₃ and NiO, and two possible mechanisms are proposed: (a) traditional heterojunction-type II and (b) Z-scheme type. The CB and VB potentials of NiO (−2.55 eV vs. NHE and 0.53 eV vs. NHE) are more negative than those of α-MoO₃ (0.02 eV vs. NHE and 3.27 eV vs. NHE, respectively). If the charge transfer

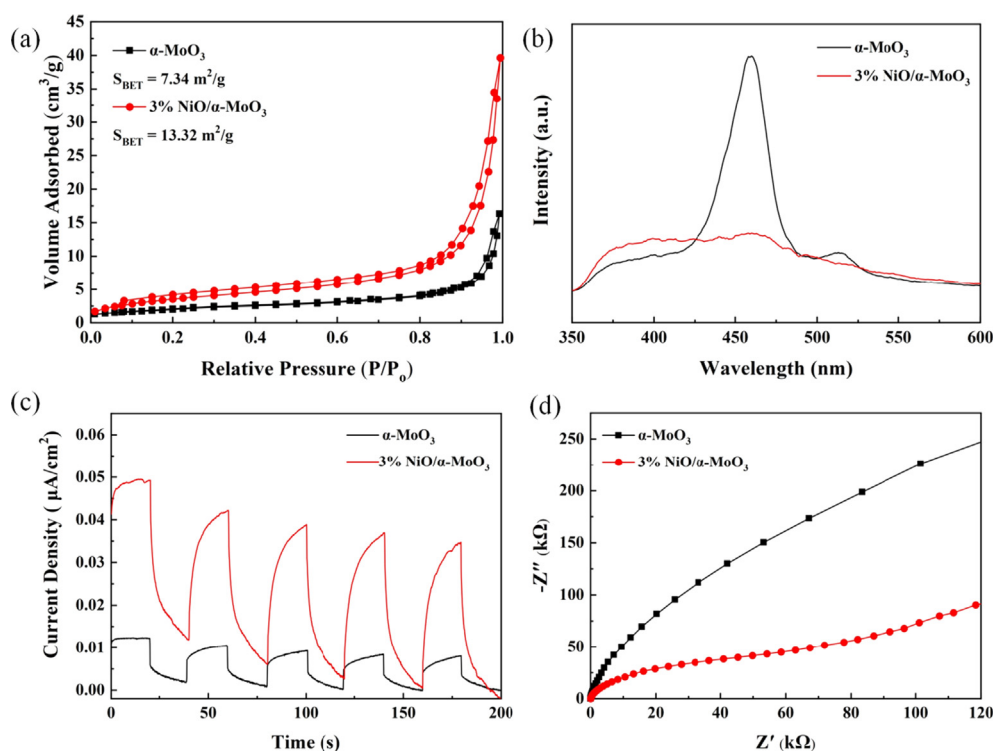

Fig. 8 (a) Nitrogen adsorption–desorption isotherms, (b) PL spectra, (c) transient photocurrent responses and (d) EIS Nyquist spectra of bare α-MoO₃ and 3% NiO/α-MoO₃ heterojunction.
Fig. 9 (a) Active species trapping experiments of MB degradation over 3% NiO/α-MoO₃; (b) ESR spectra of 3% NiO/α-MoO₃ heterojunction: DMPO- •O₂⁻ in methanol dispersion and DMPO- •OH in aqueous dispersion.

route follows the traditional type-II mechanism in Fig. 10(a), the electrons in the CB of NiO will transform to the CB of α-MoO₃ and holes in the VB of α-MoO₃ move to the VB of NiO. Consequently, the electrons will accumulate on the CB of α-MoO₃, and the holes will accumulate on the VB of NiO. However, the system may not have high reduction potential (only 0.02 eV for CB of α-MoO₃) and oxidation potential (only 0.53 eV for VB of NiO) for generating •O²⁻ (−0.33 eV) and •OH radicals (1.99 and 2.74 eV) (Li et al., 2020; Zeng et al., 2021). This presumption is contradictory to the ESR results, in which •O²⁻ and •OH are detected to be the main active species during the photodegradation process. Thus, it is supposed that a more reasonable Z-scheme photoelectron migration emerges in the p-n heterojunction.

NiO is a p-type material, and the Fermi level is close to the VB; α-MoO₃ is a n-type material, and the Fermi level is near to the CB (Teng et al.,2017; Sun et al., 2016; Zhao et al.,2021; Wang et al., 2020). As shown in Fig. 10(b), E_F of NiO is higher than that of α-MoO₃. After contact of NiO with α-MoO₃, electrons will transfer from NiO to α-MoO₃ until unified E_F is fabricated. At the equilibrium state, NiO loses electrons and is positively charged; while α-MoO₃ acquires electrons and forms an electron-rich layer (Xu et al., 2019). This process forms an internal electric field at the interface and induces energy band bending (Deng et al., 2021). When NiO/α-MoO₃ p-n heterojunction is irradiated by the simulated sunlight, the photoin-

duced electrons at the CB of α-MoO₃ will rapidly transfer to the VB of NiO and recombine with the photoexcited holes at the VB of NiO. Therefore, the corresponding photogenerated electrons and holes are left at the CB of NiO and the VB of α-MoO₃, respectively, which retains the high oxidation and reduction capabilities of the NiO/α-MoO₃. Meanwhile, useless photogenerated electrons (from the CB of α-MoO₃) and holes (from the VB of NiO) are consumed relatively, and useful charge carriers are preserved effectively through the intimate heterojunction interface, which can be sufficiently derived in the photocatalytic system (Li et al., 2019). Therefore, •O₂⁻ and •OH should be the main active species in the reaction and degrade MB, which was consistent with the result of ESR. This Z-scheme heterojunction not only effectively promote the separation of photogenerated charges, but also retain the prominent redox potential (Muñoz-Batista et al., 2016; Zheng et al., 2019).

4. Conclusions

In summary, the Z-scheme NiO/α-MoO₃ p-n heterojunction has been prepared through a two-step hydrothermal route. And the decoration of NiO is demonstrated to be a promising approach to design highly active and stable α-MoO₃ based photocatalysts. According to the SEM/TEM/EDX/XPS analysis, the NiO nanoparticles are successfully grown on α-MoO₃ nanobelts, forming heterojuction at the interface of

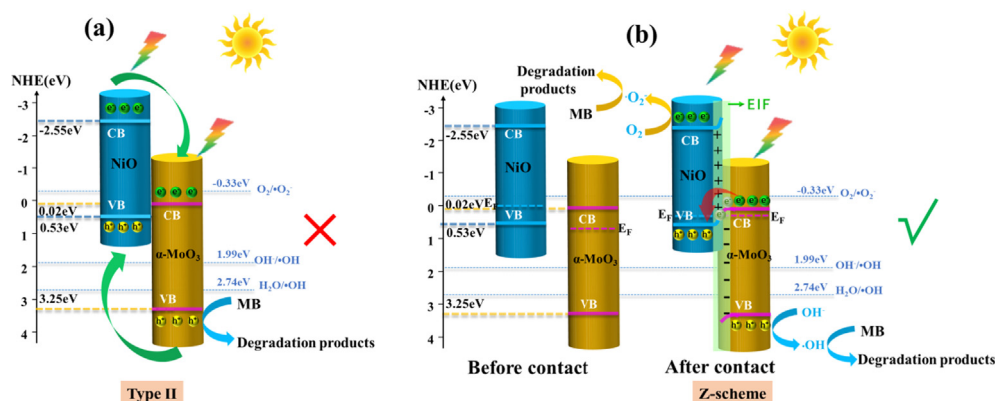

Fig. 10 Two models of charge migration for NiO/α-MoO₃ p-n heterojunction: (a) traditional heterojunction-type II (b) and Z-scheme type.

NiO and α-MoO₃. Compared with pure α-MoO₃ nanoblets, the NiO/α-MoO₃ heterojunction exhibits enhanced photocatalytic activity, achieving 96.5% photocatalytic efficiency within 2 h under simulated solar light irradiation. Meanwhile, the heterostructures retain relatively consistent activity after five repeat cycles. A Z-scheme charge transfer process between NiO and α-MoO₃ can be inferred, which significantly accelerates the charge separation. This study provides a reference for the future research of MoO₃-based p-n heterojunction photocatalysts.
